Land Surface Assimilation Operational at ECCC

- The initialization of soil moisture and surface temperatures is based upon the assimilation of near-surface temperature and humidity observations (Mahfouf 1991; Bélair et al. 2003).
- These near-surface observations are not direct measures of soil moisture, but their assimilation is designed to improve the estimates of surface turbulent fluxes and the resulting NWP forecasts of near-surface variables (Drusch and Viterbo 2007).
- Studies have shown that the increments added to soil moisture through screen-level temperature and humidity assimilation can lead to an overall degradation of soil moisture suggesting that the improved NWP forecasts are not necessarily the results of more skillful soil moisture simulations.

Land Surface Assimilation : Developments at ECCC

- **Observations**

- **Soil Moisture** :
- **Soil Moisture and Ocean Salinity (SMOS)**;
- **Soil Moisture Active Passive (SMAP)** ;
- **Surface Temperature** :
- Retrievals from GOES-15 and subsequently GOES-16, 17.
- Retrievals from polar orbiters, AIRS, IASI, and CRIS.

- **Land Surface Model**

Development of the Soil, Vegetation and Snow (SVS) land surface scheme (Alavi et al. 2016; Husain et al. 2016). SVS uses a tiling approach, considering separate energy budgets for bare ground and low vegetation, high vegetation, and snow within a grid cell.

Within the soil column, the vertical discretization consists of N soil layers where the vertical movement of water following the one-dimensional Richards equation for unsaturated soils.

- **Geophysical Fields**

- **Soil texture** : gridded Global Soil Dataset for Earth System Models (GSDE) (Shangguan et al. 2014).
- **Land water mask and Vegetation Fractions**: CCI-LC 2015 (ESA Climate Change Initiative) at 300 m resolution and the inland water body data at 150 m resolution.

Impacts on Soil Moisture

Evaluation period is short (2 months) but these results are consistent with more extensive, multi-year soil moisture evaluations (e.g., Reichle et al. 2017; De Lannoy et al. 2016ab).

Summary

- Analyzing soil moisture with SMOS/SMAP TBs has lead to superior correlation and STDE scores when compared to in-situ observations. Results are consistent with more extensive, multi-year evaluations.
- The improvements in simulated soil moisture result from a combination of an improved land-surface model (SVS), including geophysical fields, and the assimilation of SMOS TBs.
- Daytime TD_{2m} biases are improved (i.e., drier) in the SMAP experiments, when compared to SVS-SCREEN which are notably wetter.
- A deterioration in TD_{2m} STDE scores was found for the SMAP experiments, concentrated during the daytime period over the Northern Great Plains.
- A comparison of modelled evapotranspiration fluxes with those derived from ALEXI found a deterioration in the temporal correlations located over the same regions as for the TD_{2m} STDE scores.

The logo consists of the word "Canada" in a large serif font, with a small red maple leaf icon positioned above the letter "a".

Technical specifications : CaLDAS-Sat

- **Land-surface model** : SVS, SPS5.9-svs.5 – to be updated to SPS5.9.8 (bit pattern validates)
- **EnKF Forecast step** : 3h, 24 members
- **Resolution** : 2.5 km grid spacing, core HRDPS domain
- **Latency** : 10 h
- **Forward Model** : Community Microwave Emission Modeling Platform (CMEM) developed at ECMWF.
Needed to convert the SVS land-surface into a first-guess L-band brightness temperature.
- **Observations assimilated:**
 - Soil Moisture and Ocean Salinity (SMOS) horizontal brightness temperatures (TB)
 - GOES Skin Temperature retrievals
 - Snow depth observations from SYNOP, METAR and SWOB networks
 - Precipitation gauge observations from the METAR and SYNOP networks
- **Control and Analyzed variables:**
 - Soil moisture (layers 1-4 down to a depth of 40 cm)
 - Surface temperatures : bare ground, vegetation, and snow
 - Snow depth
 - Screen-level temperatures

Atmosphere-Land Exchange Inverse model (ALEXI)

- ALEXI is based upon thermal infrared imagery and is coupled to a two-source energy balance model (TSEB) (Anderson et al. 2007). For this study the infrared data comes from the GOES-East (13) and GOES-West (15) platforms.
- The land-surface within TSEB is treated as a composite of soil and vegetation components, where separate energy budgets are calculated for both.
- To simulate land-atmosphere feedbacks, ALEXI has been coupled to an atmospheric boundary layer model.
- Extrapolation of instantaneous evapotranspiration fluxes to daily fluxes is based upon the conservation of evaporative fraction (EF) during daylight hours (Anderson et al. 2007). EF is the ratio of the latent heat to available energy.

CaLDAS-Sat (Satellite)

- **Objective:** Produce the most accurate estimate of the land surface state, including soil moisture, surface temperatures, and snow.
- Emphasis on the assimilation of observations derived from space-based remote sensing platforms; SMOS/SMAP and GOES surface temperature retrievals.
- An Ensemble Optimum Interpolation is used for the snow analysis.
- The SVS land-surface model is used to evolve the land surface.
- Makes use of the operational HRDPS for the lower atmospheric forcing.
- The CaLDAS-Sat analyses do not feed back to the operational models at CMC.
